Abstract

With the exception of holders of default-free instruments, a key risk run by investors is credit risk. To meet the need of investors to hedge this risk, the market uses credit derivatives.

The South African credit derivatives market is still in its infancy and only the very simplistic instruments are traded. One of the reasons is due to the technical sophistication required in pricing these instruments. This dissertation introduces the key concepts of risk neutral probabilities, arbitrage free pricing, martingales, default probabilities, survival probabilities, hazard rates and forward spreads. These mathematical concepts are then used as a building block to develop pricing formulae which can be used to infer valuations to the most popular credit derivatives in the South African financial markets.

Key Terms:

Risk neutral probabilities; Arbitrage free pricing; Martingales; Default probabilities;

Survival probabilities; Hazard rates; Forward spreads; Credit derivatives; Credit default swaps; Default digital swaps; Asset swap packages
Chapter 1

Introduction

For the past decade, we have witnessed a new, sophisticated and increasingly popular development in the derivatives market – credit derivatives. Instead of the normal derivatives where prices are dependent on prices of the underlying asset, credit derivatives are instruments where their evaluations are driven by the credit risk of commercial or government entities. Essentially, the underlying asset in credit derivatives is the *credit risk* on an underlying bond, loan or other financial instrument.
1.1 Credit Risk

**Definition 1.1.1:** *Credit risk* is the risk that a borrowing entity will default on a loan, either through inability to maintain the interest servicing or because of bankruptcy on insolvency leading to inability to repay the principal itself.

When an entity defaults, the corresponding entity’s bondholders suffer a loss as the value of their asset declines, and the potential greatest loss is that of the entire bond which they hold. The extent of credit risk fluctuates as the fortunes of the entity changes in line with their own economic circumstances and the macroeconomic business cycle. The magnitude of credit risk can be described by a firm’s *credit rating*.

**Definition 1.1.2:** In personal finance, the term *credit rating* commonly refers to a score issued by a credit monitoring organisation. A person’s credit rating indicates how creditworthy he or she is. In corporate finance, a credit rating is a "grade" assigned to a bond, bond issuer, insurance company, or other entity or security to indicate its riskiness.
Bond rating agencies like Moody’s and Standard & Poor’s (S&P) provide a service to investors by grading fixed income securities based on current research and prevailing market conditions. The rating indicates the likelihood that the issuer will default either on interest or capital payments.

- For S&P, the ratings vary from AAA (the most secure) to C.
- For Moody’s, the ratings vary from Aaa (the most secure) to D.

Only bonds with a rating of BBB or better are considered to be suitable for investment by institutions. Anything below BBB, is considered to be junk, or below “investment grade”. Bond ratings are periodically revised based on most recent available information. The following table gives a brief summary of the ratings issued by Moody’s and S&P.
### Ratings and Bond Ratings

<table>

Ratings agencies undertake a formal analysis of the various corporate entities, after which a rating is announced. The analyses on an entity by the rating agencies are fairly comprehensive and the issues considered in the analysis most frequently include the following:

- the financial position of the firm itself, for example, its balance sheet position and anticipated cash flows and revenues.
- other qualitative firm-specific issues such as the quality of the management and succession planning.
• an assessment of the firm's ability to meet scheduled interest and principal payments, both in its domestic and foreign currencies.

• the outlook for the industry and the competition within it.

• general assessments for the domestic economy.

Hence credit ratings can be used as an indication of the magnitude of an entity's credit risk.

Another measure of credit risk (a market driven approach) is the credit risk premium, which is the difference between yields on the same-currency government benchmarks bonds and corporate bonds. If we consider a local investment in a local bond, government benchmark bonds can be assumed to be default-free, as the government can print more money in order to fund any shortfall in its obligations. This premium between a corporate bond and a similar government benchmark bond is the compensation required by investors for holding bonds that are not default-free. The credit premium required will fluctuate as individual firms and sectors are perceived to offer improved or worsening credit risk, and as the general health of the economy improves or worsens. For example, the graph below illustrates the variability in credit
spread premium in the South African corporate bond market. We can observe that there is a reasonable spread differential between each of the credit ratings. This can be associated to investors demanding higher yields for greater credit risk taken on. Furthermore, the credit spreads in recent years indicate an increased credit risk environment. This can be associated to the recent sub-prime credit crises experienced offshore.

Local bond spreads per rating band

Source: RMB FICC Research, 1 October 2009
Some practical examples of credit risk are as follows:

- A holder of a corporate bond bears the risk that the market value of the bond will decline due to a deterioration in the credit quality of the issuer and hence a decline in the credit rating of the issuer.
- A bank may suffer a loss if a bank's debtor defaults on payments of the interest due and (or) the principal amount of the loan. This is typically dominant in a home loan or auto loan transaction.

Credit risk can be thought of as a subset of the vast ocean of financial risk. We now attempt to establish its position in the world of financial risk and provide a graphical breakdown of the constituents that make up credit risk as follows:
Financial risk is a measure of adverse changes in a financial position as a result of a changing economic environment. Broadly, financial risk may be divided into market risk and credit risk.

**Definition 1.1.3:** Market risk is the risk of changes in the market price of a defaultable asset, even if no default occurs.

Credit risk may be further categorised into the following four components:

- **Arrival risk:** this is a term for the uncertainty whether a default will occur or not. A common measure of arrival risk is the probability of default.

- **Timing risk:** refers to the uncertainty about the exact time of default. Timing risk is a more detailed and specific measure than arrival risk, as knowledge about the time of default includes knowledge about the arrival risk for all possible time horizons.
• **Recovery risk:** describes the uncertainty about the severity of the losses if a default has occurred. Market convention is to express the recovery rate of a bond or loan as the fraction of the notional value of the claim that is actually paid to the creditor.

• **Default correlation risk:** describes the risk that several obligors default together. This would imply joint arrival risk which is described by the joint default probabilities over a given time horizon, and joint timing risk which is described by the joint probability distribution function of the times of default.
1.2 Credit Derivatives

Before we formally introduce a credit derivative, a few key definitions are required:

**Definition 1.2.1:** A *credit event* is a general default event related to a legal entity’s previously agreed financial obligation. In this case, a legal entity fails to meet its obligation on any significant financial transaction (e.g. coupon on a bond it issued).

**Definition 1.2.2:** *Reference entity* or *reference credit* refers to one (or several) issuer(s) whose defaults trigger the *credit event*. This can be one or several defaultable issuers.

**Definition 1.2.3:** *Reference obligations* or *reference credit assets* are a set of assets issued by the *reference credit*. They are required for the determination of the credit event and for the calculation of the recovery rate.

The events triggering a credit derivative are defined in a bilateral swap confirmation which is a transaction document that typically refers to an ISDA (International Swaps and Derivatives Association) master agreement previously executed between the two
counterparties. There are several standard credit events which are typically referred to in credit derivative transactions:

- Bankruptcy
- Failure to Pay
- Restructuring
- Repudiation
- Moratorium

**Definition 1.2.4:** Default payments are the payments which have to be made if a credit event has occurred.

Credit Derivatives were introduced to the market in the beginning of the 1990’s. Despite their short history their use and applications has grown rapidly. Credit derivatives are now used not only by banks, but also by various funds, insurance companies and even corporations, in order to separate and trade credit risk. The term credit derivatives can be used for a broad range of securities. Schonbucher
(2003) gives one definition of credit derivatives which covers the different securities discussed here:

**Definition 1.2.5:** A credit derivative is a derivative security that has a payoff which is conditioned on the occurrence of a credit event. The credit event is defined with respect to a reference credit (or several reference credits), and the reference credit asset(s) issued by the reference credit. If the credit event has occurred, the default payment has to be made by one of the counterparties. Besides the default payment, a credit derivative can have further payoffs that are not default contingent.

(Schonbucher 2003, p8)

Credit derivatives in their simplest form are bilateral contracts between a buyer and seller under which the seller sells protection against pre-agreed events occurring in relation to a third party (usually a corporate or sovereign) known as a reference entity. The reference entity will not (except in certain very limited circumstances) be a part to the credit derivatives contract, and will usually be unaware of the contract’s existence.
One of the most popular credit derivatives in the South African financial markets is the credit default swap (CDS). Hence, the last section of the introduction is dedicated to understanding the cash flow dynamics of a CDS.
1.3 Credit Default Swaps (CDS)

Credit default swaps transfer the potential loss on a reference asset that can result from specific credit events such as default, bankruptcy, insolvency and credit rating downgrades. Marketable bonds are the most popular form of reference asset because of their price transparency. While bank loans have the potential to become the dominant form of reference asset, this is impeded by the fact that loans are more heterogeneous and illiquid than bonds. Credit default swaps involve a protection buyer, who pays a periodic or upfront fee to a protection seller in exchange for a contingent payment if there is a credit event. The fee is usually quoted as a basis point multiplier of the nominal value.

Some default swaps are based on a basket of assets and pay out on a first to default basis whereby the contract terminates and pays out if any of the assets in the basket are in default. Default swaps are the largest component of the global credit derivatives market.

However structured, the credit default swap enables one party to transfer its credit exposure to another party. Banks may use default swaps to trade sovereign and
corporate credit spreads without trading the actual assets themselves; for example
someone who has gone long a default swap (the protection buyer) will gain if the
reference assets’ obligor suffers a rating downgrade or defaults, and can sell the
default swap at a profit if he can find a suitable counterparty. This is because the
cost of protection on the reference asset will have increased as a result of the credit
event. The original buyer of the default swap need never have owned a bond issued
by the reference assets’ obligor. The maturity of the credit default swap does not
have to match the maturity of the reference asset and in most cases does not. On
default, the swap is terminated and default payment by the protection seller or
guarantor is calculated and handed over. The guarantor may have the asset
delivered to him and pay a pre-specified proportion of the nominal value, or may cash
settle the swap contract.
A Cash Flow Example:

As an example we use a hypothetical transaction between an investment company and XYZ bank. In this case the investment company sells protection (takes on credit risk) on R10 million General Motors to XYZ bank. Let’s assume that credit protection is written on 100% of the nominal value.

The term of the transaction is 5 years. In return for the credit protection on General Motors, which the investment company is providing over this five-year period, XYZ bank agrees to pay a fixed fee of 1.6% (160 basis points) per annum payable quarterly.

Let’s assume that settlement is physical. Thus, should a credit event occur, XYZ bank would be able to deliver any qualifying senior unsecured General Motors paper to the investment company in return for a R10 million payment and then the contract (and all future payments) would terminate. The charts below illustrate two potential scenarios for this transaction:
In chart A, no General Motors credit event occurs and XYZ bank simply continues to pay the 160 basis points annual premium to the investment company. For XYZ bank there is, therefore, a negative accrual relating to these payments.
Chart B however depicts a scenario in which a credit event occurs two years into the transaction. In this case XYZ bank pays the investment company the premium of 160 basis points for the two years preceding the credit event and then receives R 10 million from the investment company in return for delivering any qualified senior unsecured debt obligation with a notional amount of R 10 million. Following such credit event, it is likely that General Motors’ debt would be trading substantially below par – and the investment company would be expected to bear the loss resulting from the diminution of value. The table below summarises the cash flows:

### Example Cashflows under “no default” and Credit Event At 2 Years Scenarios

</tbody>
</table>

Now that we have introduced the underlying terminology, we proceed to the focal point of this dissertation, which is a logical argument to the mathematical concepts required to develop credit derivative pricing models.
Chapter 2

Bonds, Credit Spreads and Implied Default

Probabilities

A Bond can be thought of as a securitised version of a loan. The major difference is that bonds are tradeable in small denominations. This tradeability feature of bonds opens access to a much larger number of lenders due to the following advantages over conventional loans:

- each lender can lend small amounts.
- most bonds are more standardised than loans.
• Lenders do not need to remain invested for the whole borrowing period as
  they can trade their bonds in the secondary market.

As a result the issuer can sell the bonds at competitive prices, which usually results
in better conditions than bilateral negotiations with just a few potential loan creditors.

The price of defaultable bonds contains extremely important information about the
markets perceived assessment of the issuer’s default risk.

The three most significant and popular types of bonds are defined as follows:

**Definition 2.1:** *Fixed-coupon bonds* are bonds where the coupon amounts are fixed
in advance, and the notional is repaid in full at maturity of the bond.

**Definition 2.2:** *Par floaters* are bonds where the coupon amounts are linked to a
benchmark short-term interest rate plus a constant spread. Usually, the spread is
chosen such that the price of the par floater is initially at par.
**Definition 2.3:** Zero-coupon bonds are bonds with no coupon payments. In order to compensate investors, they are usually issued at a discount to par.

We now begin to introduce some of the key mathematical concepts. We begin by setting the probabilistic foundations by defining the following:

**Definition 2.4:** A sample space or universal sample space, often denoted, $\Omega$, of an experiment or random trial is the set of all possible outcomes.

**Definition 2.5:** A non-empty collection of subsets $F$ of $\Omega$ is called a $\sigma$–algebra if:

1. $A \in F \Rightarrow \overline{A} \in F$,
2. for any countable sequence $\{A_i\}$ from $F$, $\bigcup A_i \in F$,
3. $\emptyset \in F$, where $\emptyset$ denotes the impossible event.

**Definition 2.6:** Suppose $F$ is a $\sigma$–algebra. If for any sequence $A_1, A_2, \ldots, A_n, \ldots$ of disjoint sets in $F$, one has:

$$\mu \left( \bigcup_{n=1}^{\infty} A_n \right) = \sum_{n=1}^{\infty} \mu(A_n),$$

we say that $\mu$ is countably additive or $\sigma$–additive.
**Definition 2.7:** A measurable space $\Omega, F$ consists of a sample space $\Omega$ consisting of possible outcomes $\omega$ and a collection $F$ of subsets of $\Omega$ called a $\sigma$-algebra. A countably additive mapping $\mu : F \rightarrow \mathbb{R}^+$ is called a measure on $\Omega, F$.

**Definition 2.8:** A probability measure $Q$ is a normed measure over a measurable space $\Omega, F$; that is, $Q$ is a real-valued function which assigns to every $A \in F$ a number such that:

1. $Q(A) \geq 0$ for every $A \in F$;
2. $Q(\Omega) = 1$;
3. for any denumerable sequence $\{A_n\}$ of disjoint events from $F$,
   
   $$Q\left(\bigcup_{n=1}^{\infty} A_n\right) = \sum_{n=1}^{\infty} Q(A_n)$$

The triple $(\Omega, F, Q)$ is called a probability space.

**Definition 2.9:** A collection $(F_t)_{t \in T}$ of sub-$\sigma$-algebras of $F$ is called a filtration if $F_s \subseteq F_t$ for all $s \leq t$. A stochastic process $M$ defined on $(\Omega, F, Q)$ and indexed by $T$ is called adapted to the filtration if for every $t \in T$, the random variable $M_t$ is $F_t$-measurable.
The filtration can be thought of as a flow of information. The $\sigma$-algebra $F_t$ contains the events that can happen up to time $t$. An adapted process is a process that does not look into the future. If $M$ is a stochastic process, the filtration $(F^M_t)_{t \in T}$ is defined by:

$$F^M_t = \sigma(M_s : s \leq t).$$

We call this filtration the filtration generated by $M$, or the natural filtration of $M$.

Intuitively, the natural filtration of a process keeps track of the history of the process. A stochastic process is always adapted to its natural filtration.

**Definition 2.10:** In general, if $M$ is a random variable defined on a probability space $(\Omega, F, Q)$, then the expected value of $M$, denoted by $E(M)$ or $E_Q(M)$, is defined as follows:

$$E(M) = \int_{\Omega} MdQ$$
Definition 2.11: (Martingale): A stochastic process \( M_t \) adapted to \( F_t \), and satisfying \( E( | M_t | ) < \infty, \forall t \in [0, T] \) is called a \( Q \) - submartingale if:

\[
E_Q(M_T | F_t) \geq M_t, \quad \forall t \in [0, T],
\]

and a \( Q \) - supermartingale if:

\[
E_Q(M_T | F_t) \leq M_t, \quad \forall t \in [0, T],
\]

\( M_t \) is a martingale if it is both a submartingale and a supermartingale, i.e., if

\[
E_Q(M_T | F_t) = M_t.
\]

A martingale can be thought of as a stochastic process such that the conditional expected value (a definition can be found in Probability and Measure, page 445) of an observation at some time \( T \), given all the observations up to some earlier time \( t \), is equal to the observation at that earlier time \( t \).

Definition 2.12: (Martingale measure): Let \( Q \) be a probability measure. If for every dividend free traded asset with price process \( p(T) \), the discounted price process \( p(T)/b(T) \) is a martingale under \( Q \), then \( Q \) is called a martingale measure (or spot-martingale measure). Here \( b(T) = \exp \left( \int_t^T r(s) ds \right) \) is the value of the default-free continuously compounded bank account at time \( T \), and the default free-continuously compounded discount factor from \( t \) to \( T \) is defined as \( \beta(T) = 1/b(T) \).
Arbitrage free pricing is a fundamental assumption in deducing pricing equations for derivatives. Arbitrage refers to the practice of taking advantage of a price differential between two or more financial instruments; striking a combination of matching deals that capitalizes upon the imbalance. If the market prices do not allow for profitable arbitrage, the prices are said to constitute an arbitrage equilibrium or arbitrage-free market. An arbitrage equilibrium is a precondition for a general economic equilibrium.

The central importance of the martingale measure in mathematical finance is based upon the fact that the existence of an equivalent martingale measure is equivalent to the absence of arbitrage in the underlying market. (see Harrison and Pliska, 1981, for technical conditions under which this is true).

**Definition 2.13:** Let \( \{F_t\}_{t \geq 0} \) be a filtration with respect to a non-null \( \Omega \) space, which belongs to the probability space \( (\Omega, F, Q) \). Then the quadruple \( (\Omega, \{F_t\}_{t \geq 0}, F, Q) \) is said to be the *filtered probability space* with respect to filtration \( \{F_t\}_{t \geq 0} \).
The analysis proceeding takes place in a filtered probability space \((\Omega, (F_t)_{t \geq 0}, F, Q)\) under the risk-neutral probability measure (spot martingale measure) \(Q\), and all probabilities and expectations are taken under the measure \(Q\). In order to develop the framework, we define as follows:

**Definition 2.14:**

Assume that \(A\) is any subset of \(F\) i.e. \(A \in F\). The *indicator function* of \(A\) is denoted by \(1_{[A]}\). Hence,

\[
1_{[A]}(\omega) = \begin{cases} 
1 & \text{if } \omega \in A \\
0 & \text{otherwise}
\end{cases}
\]

**Definition 2.15:**

We denote the time of default as \(\tau\), and the *survival indicator function* as \(I(t)\), where \(I(t)\) is defined as \(I(t) = 1_{[\tau > t]}\). Hence:

\[
I(t) = 1 \text{ if } \tau > t \text{ (if default occurs after time } t) \\
\]

and

\[
I(t) = 0 \text{ if } \tau \leq t \text{ (if default occurs before or at time } t) \\
\]
**Definition 2.16:**

We denote default free zero coupon bond (ZCB) prices for all maturities \( T > t \) as follows:

\[
B(t, T) = \text{Price of a ZCB at time } t, \text{ which is paying a notional of 1 at } T
\]

**Definition 2.17:**

We denote defaultable zero coupon bond prices for all maturities \( T > t \), if \( T > t \) as follows:

\[
\overline{B}(t, T) = \text{Price of a ZCB at time } t, \text{ if the time of default is beyond } t
\]

In order to ensure the absence of arbitrage the following two conditions are required:

1. **Defaultable bonds are always worth less than default free bonds of the same maturity.**

   Hence,

   \[
   0 \leq \overline{B}(t, T) \leq B(t, T), \quad \forall t < T
   \]

Most defaultable bonds are not secured by collateral. Hence, investors of such bonds must assume not only interest rate risk but also credit risk of the issuer.
Depending on the credit quality and probability of default of the issuer, investors will usually demand a discount in value to an identically traded default free bond. (usually found in the form of a government benchmark bond). Hence, we don’t restrict ourselves by the above condition, as this is also an investor behavioural phenomenon.

2. **Zero coupon bond prices are a decreasing, non-negative function of maturity,**

\[ \bar{B}(t,t) = 1 = B(t,t) \]

Hence,

\[ B(t,T_1) \geq B(t,T_2) > 0 \quad \text{and} \quad \bar{B}(t,T_1) \geq \bar{B}(t,T_2) > 0 \quad \forall t < T_1 < T_2, \quad \tau > t \]

Similarly, this is also an investor behavioural phenomenon as investors demand lower yields for bonds with shorter maturities, assuming a constant term structure of interest rates. Hence, this would imply that bonds with shorter maturities will be priced higher, since bond yields and bond prices and inversely related.

In order to further develop the framework, the following assumptions are made:
Assumption 2.1:

- At time $t$, the defaultable and default-free zero-coupon bond prices of all maturities $T > t$ are known. This assumption is not unreasonable as most bond exchanges throughout the world, would be able to provide this information as at close of any business day.

- The bond prices are arbitrage-free. This is also not an unreasonable assumption, as if arbitrage opportunities did occur, traders would take advantage of this momentarily and this would consequently result in arbitrage-free prices.

- The defaultable zero-coupon bonds have no recovery at default. The price at time $t$ of a defaultable bond with maturity $T$ can be represented as follows:

$$I(t)\bar{B}(t,T) = \bar{B}(t,T) \text{ if } \tau > t$$

and

$$I(t)\bar{B}(t,T) = 0 \text{ if } \tau <= t \text{ (since default has occurred and the recovery value is zero)}$$
**Assumption 2.2:**

The default-free interest-rate dynamics are independent of the default time, under the probability measure $Q$. Hence,

$$B(t,T) \mid T \geq t \text{ and } \tau \text{ are independent under } (\Omega, F, Q).$$

We now state the first fundamental theorem of Asset Pricing, which will be critical to formulate our results. A proof can be found in the seminal paper due to Harrion and Pliska (1981, Stochastic Processes and Their Applications, 11, 215-260)

**Theorem 2.1: (First Fundamental Theorem of Asset Pricing)**

A financial market with time horizon $T$ and price processes of the risky asset and riskless bond given by $S_t, \ldots S_T$ and $B_t, \ldots B_T$, respectively, is arbitrage-free under the probability $P$ if and only if there exists another probability measure $Q$ such that:

1. For any event $A$, $P(A) = 0$ if and only if $Q(A) = 0$. Hence, $P$ and $Q$ are equivalent probability measures.

2. The discounted price process, $X_0 = S_0 / B_0, \ldots, X_T = S_T / B_T$ is a martingale under $Q$. 
2.1 Pricing the default-free zero-coupon Bond

Using theorem [2.1], we can deduce that under the spot martingale measure, the price of every contingent claim is given by the expected value of its discounted expected payoff. Hence, we can price the default-free zero coupon bond as follows:

\[
B(t, T) = E[e^{-\int_t^T r(s)ds}.1] = E[\beta(T)], \text{ where } \beta(T) \text{ is as defined in definition [2.12]}
\]

where \( r(s) \) is the default-free continuously compounded short rate.

2.2 Pricing the defaultable zero-coupon Bond

For a defaultable zero-coupon bond, the payoff is 1 only if the obligor did not default by time \( T \). If default did occur by time \( T \), clearly, the value of the bond is zero.

Hence, \( I(t) = 1_{\{t>T\}} \)

\[
I(T) = 1 \text{ if } \tau > T \text{ (if default occurs after time } T) \\
\text{ and } \\
I(T) = 0 \text{ if } \tau \leq T \text{ (if default occurs before or at time } T) 
\]
Therefore, the price of the defaultable zero-coupon bond at time \( t < \tau \) is:

\[
\overline{B}(t, T) = E[e^{-\int_{t}^{\tau} r(s) ds} I(T)]
\]

Equation [2]

\[= E[\beta(T) I(T)], \text{ where } \beta(T) \text{ is as defined in definition } [2.12]\]

Using assumption [2.2] (independence), we can factor the expectation operator as a product of expectations in equation [2]. Hence:

\[
\overline{B}(t, T) = E[e^{-\int_{t}^{\tau} r(s) ds} I(T)]
\]

\[= E[e^{-\int_{t}^{\tau} r(s) ds}] E[I(T)]
\]

\[= E[e^{-\int_{t}^{\tau} r(s) ds} 1] E[I(T)]
\]

Equation [3]

Substituting equation [1] in equation [3]:

\[= B(t, T) E[I(T)]
\]

\[= B(t, T) P(t, T)
\]

Equation [4]

where \( P(t, T) \) in equation [4] is the implied probability of survival in the interval \([t, T]\).

The implied probability of survival will be discussed further in chapter 3.
Chapter 3

An extension to the Framework: Survival

Probabilities

This chapter is an extension to the framework developed in chapter 2. In formulating equation [4], we briefly mentioned the probability of survival. We now proceed to give a formal definition of the probability of survival as follows:
**Definition 3.1:** (Implied survival probability) Let the time of default, $\tau$, be greater than $t$, i.e., $\tau > t$.

- The implied survival probability from $t$ to $T$, where $T \geq t$, at time $t$ is given by the ratio of the defaultable and default-free zero coupon bond prices, as follows:

$$P(t,T) = \frac{\overline{B}(t,T)}{\underline{B}(t,T)}$$

where $B(t,T)$ and $\underline{B}(t,T)$ is as defined in equation [1] and equation [2] respectively.

- The *implied default probability* over the interval $[t,T]$ is denoted by,

$$P_{\text{def}}(t,T)$$

and is defined as follows:

$$P_{\text{def}}(t,T) = 1 - P(t,T)$$

If the prices of zero-coupon bonds for all maturities are available (as discussed in assumption 2.1), then using definition 3.1, we can obtain the implied survival probabilities for all maturities.
We now briefly mention some of the important properties of implied survival probabilities $P(t, T)$:

- $P(t, t) = 1$ and $P(t, T)$ is non-negative and decreasing in $T$.
- $P(t, \infty) = 0$
- Normally $P(t, T)$ is continuous in its second argument, except if an important event scheduled at some time $t < T_i < T$ has a direct influence on the survival of the obligor. An example of such an event would be a coupon payment date.
- Viewed as a function of its first argument, all survival probabilities for fixed maturity dates will tend to increase.

In order to analyse the default risk over a given time interval in the future, we need to introduce the concept of a *conditional survival probability*. First, let’s consider conditional probabilities as follows:
Definition 3.2: (Conditional probability) Given a probability space $(\Omega, F, P)$ and two events $A, B \in F$ with $P(B) > 0$, the conditional probability of $A$ given $B$ is defined by:

$$P(A \mid B) = \frac{P(A \cap B)}{P(B)} \quad \text{Equation [7]}$$

If $P(B) = 0$, then $P(A \mid B)$ is undefined (see Borel-Kolmogorov paradox).

We now define the following events:

- $A$: Survival until $T_2$
- $B$: Survival until $T_1$

Hence, $A \cap B$ will denote survival until $T_1$ and survival until $T_2$. If we assume that $T_1 < T_2$, $A \cap B = A$, since event $B$ is contained in $A$. In other words, if the obligor survives until $T_2$, he must also have survived until $T_1$. Hence, applying equation [7], the conditional probability of $A$ given $B$ is as follows:

$$P(A \mid B) = \frac{P(t, T_2)}{P(t, T_1)}, \text{ for } T_1 < T_2 < T$$
Similarly, we can now define the following:

**Definition 3.3:** (conditional survival probability) The conditional survival probability over the interval \([T_1, T_2]\) as seen from \(t\), given survival over \([t, T_1]\), is as follows:

\[
P(t, T_1, T_2) = \frac{P(t, T_2)}{P(t, T_1)}, \text{ where } t \leq T_1 \leq T_2
\]  

Equation [8]

As a consequence of the above definition, we can now define the *conditional default probability* as:

\[
P_{\text{def}}(t, T_1, T_2) = 1 - P(t, T_1, T_2)
\]  

Equation [9]

---

**Let’s consider the following example, assuming zero recovery:**

Define:

- \(y(T)\): is the yield on a \(T\)-year *corporate* zero-coupon bond.
- \(y_1(T)\): is the yield on a \(T\)-year *risk-free* zero-coupon bond.
- \(\tau\): is the random time of default
Using equation [2], the present value of a $T$-year corporate zero-coupon bond with a principal of 100 can be quantified as follows:

$$\bar{B}(0, T) = 100e^{-y(T)T}$$  \hspace{1cm} \text{Equation [10]}

Similarly, using equation [1], the present value of a $T$-year risk-free zero-coupon bond with a principal of 100 can be quantified as follows:

$$B(0, T) = 100e^{-y(T)T}$$  \hspace{1cm} \text{Equation [11]}

Next, the probability that the corporation will default between time zero and time $T$, can be computed using equation [6] as follows:

$$P_{\text{def}}(0, T) = 1 - P(0, T)$$

$$= 1 - \frac{\bar{B}(0, T)}{B(0, T)}$$, using the relationship in equation [5]

$$= 1 - \frac{100e^{-y(T)T}}{100e^{-y(T)T}}$$, substituting from equation [10] and [11]
Next, the conditional probability of default between \( T_1 \) and \( T_2 \) as seen from time 0,

can be computed as follows:

\[
P_{\text{def}}(0, T_1, T_2) = 1 - P(0, T_1, T_2), \text{ using equation [9]}
\]
\[
= 1 - \frac{P(0, T_2)}{P(0, T_1)}, \text{ using definition [3.3]}
\]
\[
= 1 - \frac{B(0, T_2)}{B(0, T_1)}, \text{ using equation [5]}
\]
\[
= 1 - \frac{100e^{-\gamma(T_2)T_2}}{100e^{-\gamma(T_1)T_1}}, \text{ using equation [10] and [11]}
\]
\[
= 1 - e^{-\gamma(T_2)T_2}e^{\gamma(T_1)T_1}e^{-\gamma(T_1)T_1}e^{\gamma(T_1)T_1}
\]
\[
= 1 - e^{-T_2(y(T_2) - y(T_1))}e^{T_1(y(T_1) - y(T_1))}
\]
Consider the following numerical example: Suppose that the spreads over the risk-free rate for 5-year and a 10-year BBB-rated zero-coupon bond are 130 and 170 basis points, respectively, and there is no recovery in the event of default. Using equation [12], we can compute probabilities of default as follows:

\[ P_{\text{def}}(0.5) = 1 - e^{-0.013\times5} = 0.0629 \]

\[ P_{\text{def}}(0.10) = 1 - e^{-0.017\times10} = 0.1563 \]

In the example above, information on only the spreads was sufficient to infer default probabilities. The actual yields on the underlying bonds were not required.
Chapter 4

An extension to the Framework: Hazard Rates

A popular concept in descriptive statistics and logistic regression is that of an *odds ratio*. A very basic definition of an odds ratio is as follows:

**Definition 4.1:** (odds ratio) The odds ratio of an event is the (expected) number of events divided by the (expected) number of non-events.
For example, an odds ratio of $1 : 3$ that a company will default at $T_2$ as seen from time $t$, mathematically means:

$$P_{\text{def}}(t, T_1, T_2) : P(t, T_1, T_2) = 1 : 3, \text{ where } t < T_1 < T_2$$

Borrowing this line of thought, we can define the discrete hazard rate of default:

**Definition 4.2**: (discrete hazard rate of default) The discrete implied hazard rate of default over the interval $[T, T+\Delta T]$ as seen from time $t$ is:

$$H(t, T, T + \Delta T) \Delta T = \frac{P_{\text{def}}(t, T, T + \Delta T)}{P(t, T+\Delta T)}$$  \hspace{1cm} \text{Equation [13]}

$$1 - \frac{P(t, T + \Delta T)}{P(t, T)} = \frac{P(t, T + \Delta T)}{P(t, T)} - 1, \text{ using equation [8] and [9]}

$$= \frac{P(t, T)}{P(t, T + \Delta T)} - 1$$  \hspace{1cm} \text{Equation [14]}
Rearranging equation [14], we get the following relationship:

\[ P(t, T) = P(t, T + \Delta T) [1 + H(t, T, T + \Delta T) \Delta T] \quad \text{Equation [15]} \]

**Theorem 4.1:** In the limit of \( \Delta T \to 0 \), the continuous hazard rate at time \( T \) as seen from time \( t \) is given by:

\[ h(t, T) = -\frac{\partial}{\partial T} \ln(P(t, T)) \quad \text{Equation [16]} \]

provided that the default time \( \tau > t \), and that the term structure of survival probabilities is differentiable with respect to \( T \).

**Proof:**

\[ h(t, T) = \lim_{\Delta T \to 0} \frac{H(t, T, T + \Delta T)}{\Delta T} \]

\[ = \lim_{\Delta T \to 0} \frac{1 - P(t, T, T + \Delta T)}{\Delta T P(t, T, T + \Delta T)} \quad \text{from equation [13] and [9]} \]
\[
\frac{\lim_{\Delta T \to 0} \left( \frac{1}{\Delta T} \left[ \frac{P(t, T)}{P(t, T + \Delta T)} - 1 \right] \right)}{\Delta T} \text{, from equation [14]}
\]

\[
= \lim_{\Delta T \to 0} \left( -\frac{1}{P(t, T + \Delta T)} \left[ \frac{P(t, T + \Delta T) - P(t, T)}{\Delta T} \right] \right)
\]

\[
= -\frac{1}{P(t, T)} \left[ \frac{\partial}{\partial T} P(t, T) \right]
\]

\[
= -\frac{\partial}{\partial T} \ln P(t, T)
\]
Chapter 5

An extension to the Framework: the relation to forward spreads

This chapter explores the relationship that the survival probabilities and implied hazard rates have to forward credit spreads. Let us give a formal definition of forward rates.
Definition 5.1: (default-free simply compounded forward rates) Let \( t \leq T_1 \leq T_2 \). The simply compounded forward rate over the period \([T_1, T_2]\) as seen from \( t \) is:

\[
F(t, T_1, T_2) = \frac{B(t, T_1)}{B(t, T_2)} - 1
\]

Equation [17]

This is the price of the forward contract with expiration date \( T_1 \) on a unit par zero coupon bond maturing at \( T_2 \). To prove, we re-arrange equation [17], and consider the compounding of interest rates over successive time intervals as follows:

\[
\frac{1}{B(t, T_2)} = \frac{1}{B(t, T_1)} \left(1 + F(t, T_1, T_2)(T_2 - T_1)\right)
\]

Equation [18]

where:

\[
\frac{1}{B(t, T_2)} , \text{ is the accumulation factor over } (t, T_2)
\]

\[
\frac{1}{B(t, T_1)} , \text{ is the accumulation factor over } (t, T_1), \text{ and}
\]

\[
(1 + F(t, T_1, T_2)(T_2 - T_1)) , \text{ is the simply compounded accumulation factor over } (T_1, T_2).
\]
**Definition 5.2:** (defaultable simply compounded forward rates) Assuming the notation from definition [5.1], the defaultable simply compounded forward rate over \((T_1, T_2)\) is:

\[
F(t, T_1, T_2) = \frac{B(t, T_1) - 1}{B(t, T_2)} \frac{B(t, T_2)}{T_2 - T_1}
\]

Equation [19]

**Definition 5.3:** (instantaneous continuously compounded forward rates) The default-free and defaultable instantaneous continuously compounded forward rate for \(T\) as seen from \(t\) are as follows:

\[
f(t, T) = \lim_{\Delta t \to 0} F(t, T, T + \Delta t) = -\frac{\partial}{\partial T} \ln B(t, T)
\]

Equation [20]

\[
\bar{f}(t, T) = \lim_{\Delta t \to 0} \bar{F}(t, T, T + \Delta t) = -\frac{\partial}{\partial T} \ln \bar{B}(t, T)
\]

Equation [21]
**Proposition 5.1:** The conditional probability of default per time interval \((T_1, T_2)\) is the spread of defaultable over default-free forward rates, discounted by the defaultable forward rate:

\[
P_{\text{def}}(t, T_1, T_2) = \frac{[F(t, T_1, T_2) - F(t, T_1, T_2)](T_2 - T_1)}{[1 + F(t, T_1, T_2)(T_2 - T_1)]}
\]

**Proof:** Using equation [5] and equation [8], we get the following result:

\[
P(t, T_1, T_2) = \frac{\overline{B}(t, T_2)B(t, T_1)}{\overline{B}(t, T_2)\overline{B}(t, T_1)}
= \frac{1 + F(t, T_1, T_2)(T_2 - T_1)}{1 + F(t, T_1, T_2)(T_2 - T_1)}
\]

But, from equation [9], we can deduce that:

\[
P(t, T_1, T_2) = 1 - P_{\text{def}}(t, T_1, T_2)
\]

Hence, this implies:
\[ P_{\text{def}}(t, T_1, T_2)[1 + \bar{F}(t, T_1, T_2)(T_2 - T_1)] = [\bar{F}(t, T_1, T_2) - F(t, T_1, T_2)](T_2 - T_1) \]

Re-arranging the equation, gives the result:

\[ P_{\text{def}}(t, T_1, T_2) = \frac{[\bar{F}(t, T_1, T_2) - F(t, T_1, T_2)](T_2 - T_1)}{[1 + \bar{F}(t, T_1, T_2)(T_2 - T_1)]}. \]

As a consequence, this can also be expressed as:

\[ \frac{P_{\text{def}}(t, T_1, T_2)}{T_2 - T_1} = \frac{B(t, T_2)}{B(t, T_1)} \frac{[\bar{F}(t, T_1, T_2) - F(t, T_1, T_2)]}{B(t, T_1)} \]

Equation [22]

**Proposition 5.2:** The discrete implied hazard rate of default is given by the spread of defaultable over default-free forward rates, discounted by the default-free forward rates:

\[ H(t, T_1, T_2) = \frac{\bar{F}(t, T_1, T_2) - F(t, T_1, T_2)}{1 + (T_2 - T_1)F(t, T_1, T_2)} \]
Proof: From equation [13], we get:

\[
H(t,T_1,T_2) = \frac{P_{def}(t,T_1,T_2)}{(T_2-T_1)P(t,T_1,T_2)}
\]

\[
= \frac{\bar{B}(t,T_2)[\bar{F}(t,T_1,T_2) - F(t,T_1,T_2)]}{\bar{B}(t,T_1)P(t,T_1,T_2)}, \text{ using equation [22]}
\]

\[
= \frac{B(t,T_2)}{B(t,T_1)}[\bar{F}(t,T_1,T_2) - F(t,T_1,T_2)], \text{ using equation [5] and [8]} \quad \text{Equation [23]}
\]

\[
= \frac{\bar{F}(t,T_1,T_2) - F(t,T_1,T_2)}{1+(T_2-T_1)F(t,T_1,T_2)}, \text{ using equation [17]}
\]

Proposition 5.3: The implied hazard rate of default at time $T > t$ as seen from time $t$

is given by the spread of the defaultable over the default-free continuously

compounded forward rates:

\[
\bar{f}(t,T) - f(t,T)
\]

Proof: We obtain the above relation as follows:

\[
h(t,T) = -\frac{\partial}{\partial T} \ln P(t,T))
\]

\[
= -\frac{\partial}{\partial T} \ln \frac{\bar{B}(t,T)}{B(t,T)}
\]

\[
= \bar{f}(t,T) - f(t,T)
\]
The probability of default in a short time interval \([T, T + \Delta T]\) is proportional to the length \(\Delta T\) of the interval with proportionality factor \(f(t, T) - f(t, T)\). In particular, the local default probability at time \(t\) over the next small time step \(\Delta t\) is approximately proportional to the length of the time step, with the short-term credit spread as proportionality factor. Hence, we can define as follows:

**Definition 5.4:** (local default probability) The local default probability at time \(t\) over the next small time step \(\Delta t\) is given as follows:

\[
\frac{1}{\Delta t} Q[\tau \leq t + \Delta t \mid F_t \wedge \{\tau > t\}] \approx r(t) - r(t) = \lambda(t)
\]

where \(r(t) = f(t, t)\) is the risk free short rate and \(\tilde{r}(t) = \tilde{f}(t, t)\) is the defaultable short rate.
Chapter 6

An extension to the Framework: Recovery

Modelling

We now relax the assumption of zero-recovery as assumed in the previous chapters.

We view an asset with positive recovery as an asset with an additional positive payoff at the time of default. The recovery value is the expected value of the recovery shortly after the occurrence of a default.
There are many different setups that have been proposed to model the recovery of defaultable assets. For purposes of this dissertation, I will present one particular framework which is based upon the recovery of par model first presented by Duffie [2](1998).

**Definition 6.1:** Let's define \( e(t, T, T + \Delta T) \) at time \( t < T \) as a deterministic payoff of 1 that is paid at \( T + \Delta T \) if and only if a default happens in \( (T, T + \Delta T) \):

\[
e(t, T, T + \Delta T) = E \left[ B(t, T + \Delta T) I(T) - I(T + \Delta T) \right] F_t \quad \text{Equation [24]}
\]

Note that:

\[
I(T) - I(T + \Delta T) = 1, \text{ if default occurs in } (T, T + \Delta T)
\]

and

\[
I(T) - I(T + \Delta T) = 0, \text{ otherwise}
\]

Furthermore,

\[
E \left[ B(t, T + \Delta T) I(T) \right] = E \left[ B(t, T + \Delta T) \right] E \left[ I(T) \right]
\]

\[
= B(t, T + \Delta T) P(t, T) \quad \text{Equation [25]}
\]
And,

\[ E \{ B(t, T + \Delta T) I(T + \Delta T) \} = \overline{B}(t, T + \Delta T) \]  \hspace{1cm} \text{Equation [26]}

Since, \( B(t, T + \Delta T) = \frac{\overline{B}(t, T + \Delta T)}{P(t, T + \Delta T)} \), from equation [5]

Hence, we get:

\[ e(t, T, T + \Delta T) = B(t, T + \Delta T)P(t, T) - \overline{B}(t, T + \Delta T), \] using equation [24], [25] and [26]

\[ = \overline{B}(t, T + \Delta T) \left( \frac{P(t, T)}{P(t, T + \Delta T)} - 1 \right) \]

\[ = \Delta T \overline{B}(t, T + \Delta T) H(t, T, T + \Delta T), \] using equation [14]  \hspace{1cm} \text{Equation [27]}

We now let the time step converge to zero in equation [27] in order to reach a continuous coverage of the time axis. Hence, taking the limit \( \Delta T \to 0 \), we obtain,

\[ e(t, T) \] as defined as follows:
Definition 6.2:

$$e(t, T) = \lim_{\Delta T \to 0} \frac{e(t, T, T + \Delta T)}{\Delta T}$$

$$= \bar{B}(t, T) h(t, T) \quad \text{Equation [28]}$$

$$= B(t, T) P(t, T) h(t, T) \), using equation [5]

The value of a security that pays $\pi(s)$ if a default occurs at time $s$ for all $t < s < T$ is given by:

$$\int_t^T \pi(s) e(t, s) ds$$

$$= \int_t^T \pi(s) \bar{B}(t, s) h(t, s) ds \), from equation [28]

Suppose the payoff at default is not a deterministic function $\pi(s)$ but a random variable $\bar{\pi}$ which is drawn at the time of default $\tau$. $\bar{\pi}$ is called a marked point process. For a discussion on marked point processes, see Schoncucher 2003 (Page 91).

We denote by $\pi_\tau(t, T)$, the expected value (under martingale measure $Q$-probabilities) of $\bar{\pi}$ conditional on default at $T$ and information at $t$ as follows:
$$\pi_e(t,T) = E_0[\pi | F_t \land \{ \tau = T \}]$$

We can specify any distribution for the random variable $\pi$. Then, conditional on a default occurring at time $T$ we can price a security that pays $\pi$ at default as $\pi_e(t,T)B(t,T)$. We discount the cash flow $\pi_e(t,T)$ by the risk-free discount factor.

If we do not know the time of default, the present value of the security can be computed as follows:

$$\int_t^T \pi_e(t,s)B(t,s)P(t,s)h(t,s)ds$$

$$= \int_t^T \pi_e(t,s)\overline{B}(t,s)h(t,s)ds$$, from equation [28]

Since, we do not know the time of default, we have to integrate these values over all possible default times and weigh them with the respective probability of default occurring, i.e. the density of the time of default in the continuous-time case.
Chapter 7

Application to pricing credit derivatives

This chapter focuses on the pricing dynamics of the most popular credit derivatives seen in the South African financial markets.

In order to simplify the numerical implementation, we accept a discrete grid of time points, the tenor structure:

\[ 0 = T_0, T_1, T_2, \ldots, T_K \]
The dates are indexed in increasing order \((T_k < T_{k+1})\) and the distance between two tenor dates is denoted by \(\delta_k = T_{k+1} - T_k\) for all \(0 \leq k \leq K\).

The coupon and repayment dates for bonds, fixing dates for rates, payment and settlement dates for credit derivatives all fall on \(T_k\).

From

\[
B(0,T_i) = \frac{B(0,T_{i-1})}{1 + \delta_{i-1} F(0,T_{i-1},T_i)}, i = 1,2,\ldots,k \quad \text{using equation [18]}
\]

and

\[
B(0,T_0) = B(0,0) = 1,
\]

we obtain the prices of the default-free zero coupon bonds as follows:

\[
B(0,T_k) = \prod_{i=1}^{k} \frac{1}{1 + \delta_{i-1} F(0,T_{i-1},T_i)} \tag{Equation [29]}
\]
Similarly, from

\[ P(0, T_i) = \frac{P(0, T_{i-1})}{1 + \delta_{i-1} H(0, T_{i-1}, T_i)} \], using equation [15]

We deduce the price of the defaultable zero-coupon bonds as follows:

\[ \overline{B}(0, T_k) = B(0, T_k)P(0, T_k) \]

\[ = B(0, T_k)\prod_{i=1}^{k} \frac{1}{1 + \delta_{i-1} H(0, T_{i-1}, T_i)} \] \hspace{1cm} \text{Equation [30]}

Now, let \( e(0, T_k, T_{k+1}) \) be the value of 1 unit at \( T_{k+1} \) if a default occurred in \((T_k, T_{k+1})\). Hence, from equation [27] on p.59:

\[ e(0, T_k, T_{k+1}) = \delta_k H(0, T_k, T_{k+1})\overline{B}(0, T_{k+1}) \] \hspace{1cm} \text{Equation [31]}

Note that the prices of the bonds given by equations [29], [30], and [31] above are expressed in terms of two fundamental modelling quantities as follows:
• Term structure of default-free interest rates $F(0,T)$

• Term structure of implied hazard rates $H(0,T)$

Taking the limit $\delta_i \to 0$, for all $i = 0, 1, 2, \ldots, k$ in equations [29], [30] and [31] respectively, we can express the prices in terms of continuously compounded instantaneous forward rates and hazard rates: The results are as follows:

$$B(0,T_k) = \exp\left(-\int_0^T f(0,s)ds\right)$$

$$\overline{B}(0,T_k) = \exp\left(-\int_0^T [h(0,s) + f(0,s)]ds\right)$$

$$e(0,T_k) = h(0,T_k)\overline{B}(0,T_k)$$
7.1 Defaultable fixed-coupon bonds

A defaultable fixed-coupon bond has coupon payments of $c_n$ at $T_n$, $n = 1, 2, ..., N$. It is possible for the individual fixed-coupon payments to differ slightly from each other depending on day count conventions and the bond’s specification. All the coupon payments are known in advance.

**Pricing formula:**

The price of a defaultable fixed-coupon bond can be given as follows:

$$
\overline{C}(0) = \sum_{n=1}^{N} c_n \overline{B}(0, T_n), \text{ this term represents all the coupons} \\
+ \overline{B}(0, T_N), \text{ this term represents the principal payment} \\
+ \pi \sum_{k=1}^{N} e(0, T_{k-1}, T_k), \text{ this term represent the recovery value.} \quad \text{Equation [32]}
$$

We can also represent the recovery payment as follows:
\[
\pi \sum_{k=1}^{N} e(0, T_{k-1}, T_k) = \sum_{k-1}^{N} \pi \delta_{k-1} H(0, T_{k-1}, T_k) * \overline{B}(0, T_k), \text{ using equation [31]}
\]

The recovery payments can be considered as an additional coupon payment stream of \( \pi \delta_{k-1} H(0, T_{k-1}, T_k) \).
7.2 Defaultable floater

In a defaultable par floater, the coupon payments at times $T_n$, are equal to the reference interest rate plus a spread, denoted by $s^{par}$, assuming a nominal of 1.

Let's denote $L(T_{n-1},T_n)$ as the reference interest rate applied over $(T_{n-1},T_n)$ at $T_{n-1}$, so that $1 + L(T_{n-1},T_n)\delta_{n-1}$ is the growth factor over $(T_{n-1},T_n)$. If we apply a no-arbitrage argument, we can get the following result:

$$B(T_{n-1},T_n) = \frac{1}{1 + L(T_{n-1},T_n)\delta_{n-1}}$$  \hspace{1cm} \text{Equation [33]}

If this bond trades at a value greater than $B(T_{n-1},T_n)$, this would imply that its yield is less than $L(T_{n-1},T_n)$. Hence, an arbitrage opportunity exists as a dealer can short sell these bonds and invest in other money market securities which would yield $L(T_{n-1},T_n)$. At maturity of the bond, the dealer will pay interest to the bondholders at a lower rate that what was earned on the invested money market securities.

Similarly, if this bond is trading at a value less than $B(T_{n-1},T_n)$, this would imply that its yield is more than $L(T_{n-1},T_n)$. A dealer can borrow funds at a lower rate and invest in the bond which offers a higher rate of return. Once again, an arbitrage
opportunity exists. Therefore, the relationship in equation [33] has to be true for no arbitrage opportunities to occur.

The coupon payment at $T_n$ can be represented as follows:

$$\delta_{n-1}[L(T_{n-1}, T_n) + s_{\text{par}}]$$

$$= \left[ \frac{1}{B(T_{n-1}, T_n)} - 1 \right] + s_{\text{par}} \delta_{n-1}, \text{ using equation [33]}$$

Let’s consider the payment of $\left[ \frac{1}{B(T_{n-1}, T_n)} \right]$ at time $T_n$. The present value at $T_{n-1}$ is given as follows:

$$\frac{\bar{B}(T_{n-1}, T_n)}{B(T_{n-1}, T_n)}$$

$$= P(T_{n-1}, T_n), \text{ using equation [5]}$$

We use the defaultable discount factor, since the coupon payment is exposed to credit risk over $(T_{n-1}, T_n)$. Seen at $t = 0$, the present value of $P(T_{n-1}, T_n)$ now becomes:
\[
E_Q[B(0, T_{n-1})I(T_{n-1})P(T_{n-1}, T_n)]] \\
= B(0, T_{n-1})E_Q[I(T_{n-1})P(T_{n-1}, T_n)] \text{, using assumption [2.2]} \\
= B(0, T_{n-1})P(0, T_n) \tag{34}
\]

Combine the above result with the fixed part of the coupon payment and observe the following relation:

\[
[B(0, T_{n-1}) - B(0, T_n)]P(0, T_n) = \left(\frac{B(0, T_{n-1})}{B(0, T_n)} - 1\right)\overline{B}(0, T_n) \\
= \delta_{n-1} F(0, T_{n-1}, T_n)\overline{B}(0, T_n),
\]

**Pricing formula:**

The model price of the defaultable floating-rate bond is:

\[
\overline{C}(0) = \sum_{n=1}^{N} \delta_{n-1} F(0, T_{n-1}, T_n)\overline{B}(0, T_n) \text{, default reference rate} \\
+ s^\text{par} \sum_{n=1}^{N} \delta_{n-1} \overline{B}(0, T_n) \text{, coupon spread} \\
+ \overline{B}(0, T_K) \text{, principal} \\
+ \pi \sum_{n=1}^{N} e(0, T_{n-1}, T_n) \text{, recovery} \tag{35}
\]
7.3 Credit Default Swaps (CDS’s)

CDS’s are a product within the credit derivative asset class, constituting a type of over the counter derivative. They are bilateral contracts in which a protection buyer agrees to pay a periodic fee (called a “premium”) in exchange for a payment by the protection seller in the case of a credit event (such as a bankruptcy) affecting the reference entity. The market price of the premium is therefore an indication of the perceived credit risk related to the reference entity.

A credit default swap consists of two payment legs:

\[ \text{Fixed leg:} \quad \text{The protection buyer pays a periodic fee, } \ddot{s}, \text{ for credit protection. Hence,} \]

the fixed leg consists of payments of \( \delta_{n-1} \ddot{s} \) at \( T_n \) if no default occurs until \( T_n \). The present value of the fixed leg is calculated by discounting the payments by the defaultable zero coupon bond, as the fee payments are subject to credit risk.

\[
\ddot{s} \sum_{n=1}^{N} \delta_{n-1} B(0, T_n)
\]

**Equation [36]**

\[ \text{Floating leg:} \quad \text{The protection seller pays an amount of } (1 - \pi) \text{ at } T_n \text{ contingent on default in } (T_{n-1}, T_n). \text{ The present value of the floating leg is calculated as follows:} \]

\[ \ddot{D} \]
\[(1 - \pi) \sum_{n=1}^{N} e(0, T_{n-1}, T_n) = (1 - \pi) \sum_{n=1}^{N} \delta_{n-1} H(0, T_{n-1}, T_n) \overline{B}(0, T_n), \text{ from equation [31]} \quad \text{Equation [37]}\]

where \(e(0, T_{n-1}, T_n)\) is the deterministic payoff of 1 that is paid at \(T_n\) if and only if a default happens in \((T_{n-1}, T_n)\) and \(\pi\) is the recovery rate, as a percentage of the notional.

Generally, in most CDS contracts, the market CDS swap rate is chosen such that the fixed and floating leg of the CDS has the same value, i.e. the value of the contract to the buyer must be zero when the contract is entered into. Hence, equating equation [36] and equation [37] result in the following for the fair swap rate determined at \(t = 0:\)

**Pricing formula:**

\[
\overline{s} = (1 - \pi) \frac{\sum_{n=1}^{N} \delta_{n-1} H(0, T_{n-1}, T_n) \overline{B}(0, T_n)}{\sum_{n=1}^{N} \delta_{n-1} \overline{B}(0, T_n)}
\]
Now, let’s define weights as follows:

\[ w_n = \frac{\delta_{n-1} \overline{B}(0, T_n)}{\sum_{k=1}^{N} \delta_{k-1} \overline{B}(0, T_k)} \quad \text{where} \quad n = 1, 2, 3, \ldots, N \quad \text{Equation [38]} \]

so that

\[ \sum_{n=1}^{N} w_n = 1 \quad \text{Equation [39]} \]

Then the fair swap premium rate determined at \( t = 0 \) is given by:

\[ \tilde{s} = (1 - \pi) \left( \sum_{n=1}^{N} w_n H(0, T_{n-1}, T_n) \right) \quad \text{Equation [40]} \]

We can make the following observations:

- Since, \( H \) is a function of \( P \) and \( \overline{P} \) only, hence \( \tilde{s} \) depends only on the
defaultable and default-free discount rates \( B \) and \( \overline{B} \), which are given by the
market bond prices.
• It is similar to the calculation of fixed rate in an interest rate swap (see Rebonato, 1998) as follows:

\[ s = \sum_{n=1}^{N} w_n^i F(0,T_{n-1},T_n) , \]  
\((s) is the fixed interest rate)\\

where

\[ w_n^i = \frac{\delta_{n-1} B(0,T_n)}{\sum_{k=1}^{N} \delta_{k-1} B(0,T_k)} \]  
\((n) = 1,2,3,\ldots,N)\\

When a CDS is traded, the value of the swap rate will change after the initial date, due to market movements. Let’s assume that the original CDS spread was \(s\) and the new CDS spread is now \(\tilde{s}\). The marked-to-market value of the original CDS is as follows:

\[ (\tilde{s} - s) \sum_{n=1}^{N} \overline{B}(t,T_n) \delta_{n-1} \]  
\([Equation [41]]\\

Equation [41] can be explained as follows: If an offsetting trade is entered at the current CDS rate \(\tilde{s}\), only the fee difference, \((\tilde{s} - s)\), will be received over the life of the CDS. Should a default occur, the protection payments will cancel out, and the fee difference payment will also be cancelled. The fee difference stream is defaultable and is hence discounted by \(\overline{B}(t,T_n)\). The diagrams below discuss this graphically.
Let’s assume a CDS is purchased at time 0 and an offsetting trade is entered into at time $t$. Then, if no default occurs the cash flows can be represented as follows:

<table>
<thead>
<tr>
<th>Time Line</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>............</th>
<th>t</th>
<th>............</th>
<th>N</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial CDS</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td></td>
</tr>
<tr>
<td>New CDS</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td></td>
</tr>
</tbody>
</table>

Note, the net cash flows at each point in time are the difference in the swap rates.

Similarly, the cash flows if a default occurs at $N$ are as follows:

<table>
<thead>
<tr>
<th>Time Line</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>............</th>
<th>i</th>
<th>............</th>
<th>N</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial CDS</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$\pi \cdot (1 - \pi)$</td>
<td></td>
</tr>
<tr>
<td>New CDS</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td>$s$</td>
<td></td>
</tr>
</tbody>
</table>

Note, the net cash flows at each point in time are the difference in the swap rates.

The payment at default cancels out. Hence, the only cash flows to consider are the difference in fee payments.

Hence, it can be seen that credit default swaps are useful instruments to gain exposure against spread movements, and not just against default arrival risk.
This section is dedicated to developing a logical argument for the most common market valuation approach to CDS’s. In particular, we consider the derivation of a pricing formula with commonly assumed market conventions and practices. Given, the popularity of the method, a practical example and implementation is given in the appendix.

A typical CDS contract usually specifies two potential cash flow streams; a fixed leg and a floating leg. On the fixed leg side, the buyer of protection makes a series of fixed, periodic payments of CDS premium until the maturity, or until the reference credit defaults. On the floating leg side, the protection seller makes one payment only if the reference credit defaults. The amount of a contingent payment is usually the notional amount multiplied by $1 - \pi$, where $\pi$ is the recovery rate, as a percentage of the notional. Hence, the value of the CDS contract to the protection buyer at any given point in time is the difference between the present value of the floating leg, which the protection buyer expects to receive, and that of the fixed leg, which he is expected to pay. Hence:

\[
\text{Value of CDS (to protection buyer)} = \text{PV(Floating leg)} - \text{PV(Fixed leg)} \quad \text{Equation [42]}
\]

In order to calculate these values, one needs information about the default probability of the reference credit, the recovery rate in a case of default, and risk-free discount factors.
**Fixed Leg:** On each payment date, the periodic payment is calculated as the annual CDS premium, \( s \), multiplied by \( d_i \), the accrual days (expressed in a fraction of one year) between payment dates. For example, if the CDS premium is 160 basis points per annum and payments are made quarterly, the periodic payment will be:

\[
d_{i,s} = 0.25(160) = 40
\]

However, this payment is only going to be made when the reference credit has not defaulted by the payment date. So, we have to take into account the survival probability, or the probability that the reference credit has not defaulted on the payment date. For instance, if the survival probability of the reference credit in the first three months is 90%, the expected payment at \( t_1 \), or 3 months later, is:

\[
P(t,t_1)d_{i,s} = 0.9(0.25)(160) = 36 , \ t < t_1
\]

where \( P(t,t_1) \) is the survival probability at time \( t \). Then, using the discount factor for the particular payment date, \( B(t,t_i) \), the present value for this payment is \( B(t,t_i)P(t,t_i)s_{d_i} \). Summing up PV’s for all these payments, we get:

\[
\sum_{i=1}^{N} B(t,t_i)P(t,t_i)s_{d_i}, \ t < t_1 < .... < t_N \quad \text{Equation [43]}
\]

Finally, we need to account for the accrued premium paid up to the date of default when default happens between the periodic payment dates. The accrued payment
can be approximated by assuming that default, if it occurs, occurs at the middle of the interval between consecutive payment dates. Then, when the reference entity defaults between payment date \( t_{i-1} \) and payment date \( t_i \), the accrued payment amount is \((sd_i)/2\). This accrued payment has to be adjusted by the probability that the default actually occurs in this time interval. In other words, the reference credit survived through payment date \( t_{i-1} \), but not to next payment date \( t_i \). This probability is given by:

\[
P(t; t_{i-1}) - P(t, t_i)
\]

Accordingly, for a particular interval, the expected accrued premium payment is:

\[
(P(t; t_{i-1}) - P(t, t_i))(sd_i/2)
\]

Therefore, the present value of all expected accrued payments is given by:

\[
\sum_{i=1}^{N} B(t, t_i) (P(t; t_{i-1}) - P(t, t_i))(sd_i/2) \quad \text{Equation [44]}
\]

Now, we have both components of the fixed leg. Adding equation [43] and equation [44], we get the present value of the fixed leg:

\[
PV(FixedLeg) = \sum_{i=1}^{N} B(t, t_i) P(t, t_i)sd_i + \sum_{i=1}^{N} B(t, t_i) (P(t; t_{i-1}) - P(t, t_i))(sd_i/2) \quad \text{Equation [45]}
\]
**Floating Leg:** Assume the reference entity defaults between payment date \( t_{i-1} \) and payment date \( t_i \). The protection buyer will receive the floating payment of \( 1 - \pi \), where \( \pi \) is the recovery rate. This payment is made only if the reference credit defaults and therefore it has to be adjusted by \( (P(t_{t_{i-1}}) - P(t_{t_i})) \), the probability that the default actually occurs in this time period. Discounting each expected payment and summing up over the term of a contract, we get:

\[
PV(FloatingLeg) = (1 - \pi) \sum_{i=1}^{N} (B(t_{t_i})(P(t_{t_{i-1}}) - P(t_{t_i}))) \quad \text{Equation [46]}
\]

When two parties enter a CDS trade, the CDS swap rate is set so that the value of the swap transaction is zero. Hence plugging equation [45] and equation [46] into equation [42], we arrive at the following:
Pricing formula:

\[
\sum_{i=1}^{N} B(0, t_i) P(0, t_i) s d_i + \sum_{i=1}^{N} B(0, t_i) (P(0, t_{i-1}) - P(0, t_i)) (s d_i / 2)
\]

\[
= (1 - \pi) \sum_{i=1}^{N} B(0, t_i) (P(0, t_{i-1}) - P(0, t_i))
\]

Equation [47]

Given, all the parameters, \( s \), the annual premium payment is set as:

\[
S = \frac{(1 - \pi) \sum_{i=1}^{N} B(0, t_i) (P(0, t_{i-1}) - P(0, t_i))}{\sum_{i=1}^{N} B(0, t_i) P(0, t_i) d_i + \sum_{i=1}^{N} B(0, t_i) (P(0, t_{i-1}) - P(0, t_i)) (d_i / 2)}
\]
7.5 Forward Start Credit Default Swaps

A forward start CDS is a CDS which is contracted at time $T_0$, but the actual fee payments and credit protection only start at a later time point $T_{k0}$, where $T_{k0} > T_0$.

Should a default occur some time before $T_{k0}$, the forward start CDS is cancelled with no cash flows being made.

The pricing argument for a forward start CDS is exactly as in pricing a CDS, except for the indices of the summation.

**Pricing formula:**

$$\tilde{s} = (1 - \pi) \frac{\sum_{n=k0}^{N} \delta_{n-1} H(0, T_{n-1}, T_n) \overline{B}(0, T_n)}{\sum_{n=1}^{N} \delta_{n-1} \overline{B}(0, T_n)}$$

Equation [48]
7.6 Default Digital Swaps (DDS)

Digital is a term that is used to describe electronic technology that generates, stores and processes data in terms of two states: positive and non-positive. Positive is expressed or represented by the number 1 and non-positive by the number 0. In the context of DDS, the relevance applies to the floating leg having a payoff of either 1 or 0.

A default digital swap consists of two payment legs:

**Fixed leg:** Payment of $\delta_{n-1} S^{DDS}_{T_n}$ at $T_n$ if no default until $T_n$. The value of the fixed leg is:

$$
S^{DDS}_{n-1} \sum_{n=1}^{N} \delta_{n-1} B(0, T_n)
$$

Equation [49]

**Floating leg:** A fixed payment of 1 is paid at default, independent of the actual recovery.

$$
\sum_{n=1}^{N} e(0, T_{n-1}, T_n)
\quad = \sum_{n=1}^{N} \delta_{n-1} H(0, T_{n-1}, T_n) B(0, T_n)
$$

Equation [50]
As with CDS contracts, in most DDS contracts, the market DDS swap rate is chosen such that the fixed and floating leg of the DDS has the same value. Hence, equating equation [49] and equation [50] results in the following:

**Pricing formula:**

\[
\frac{-DDS}{S} = \frac{\sum_{n=1}^{N} \delta_{n-1} H(0,T_{n-1},T_n) \overline{B}(0,T_n)}{\sum_{n=1}^{N} \delta_{n-1} \overline{B}(0,T_n)}
\]

If we define weights as in equation [38] and equation [39], then the fair swap premium rate is given by:

\[
\frac{-DDS}{S} = \sum_{n=1}^{N} w_n H(0,T_{n-1},T_n) 
\]

Equation [51]

Using equation [40] and equation [51], we can get the following result in terms of DDS and CDS fee payments. Since, DDS is independent of recovery, while CDS's
are contingent on recovery, DDS's can be considered to be more expensive than a corresponding CDS contract.

\[
\frac{-D_{DS}}{S} = \frac{1}{1 - \pi} \frac{-}{S}
\]
### 7.7 Asset Swap Packages

An asset swap package consists of a defaultable coupon bond $\overline{C}$ with coupon $\overline{c}$ and an interest rate swap. The bond’s coupon is swapped into the reference interest rate plus the asset swap rate $s^A$. An asset swap package is usually sold at par.

Asset swap transactions are driven by the desire to strip out unwanted structured features from the underlying asset.

The payoff streams to the buyer of the asset swap package can be described as follows:

<table>
<thead>
<tr>
<th>Time</th>
<th>Defaulatable Bond</th>
<th>Swap</th>
<th>Net</th>
</tr>
</thead>
<tbody>
<tr>
<td>$t = 0$</td>
<td>$-\overline{C}(0)$</td>
<td>$-1 + \overline{C}(0)$</td>
<td>$-1$</td>
</tr>
<tr>
<td>$t = t_i$</td>
<td>$\overline{c}$</td>
<td>$-\overline{c} + L_{t-1} + s^A$</td>
<td>$L_{t-1} + s^A + (\overline{c} - \overline{c})$</td>
</tr>
<tr>
<td>$t = t_N$</td>
<td>$(1 + \overline{c})^*$</td>
<td>$-\overline{c} + L_{N-1} + s^A$</td>
<td>$1^* + L_{N-1} + s^A + (\overline{c}^* - \overline{c})$</td>
</tr>
</tbody>
</table>

* denotes payment contingent on survival
We now define as follows:

\[ s(0) = \text{Fixed-for-floating swap rate (the market quote)} \]

\[ A(0) = \sum_{n=1}^{N} \delta_{n-1} B(0, T_n) \] This is the value of an annuity paying 1 unit, calculated based on observable default free bond prices.

The value of an asset swap package is set at par at \( t = 0 \), so that:

\[ \overline{C}(0) + \left(A(0)s(0) + A(0)s^A(0) - A(0)c\right) = 1 \]

The present value of the floating coupons is given by \( A(0)s(0) \). The swap continues even after default so that \( A(0) \) appears in all terms associated with the swap arrangement. Solving for \( s^A(0) \):

\[ s^A(0) = \frac{1}{A(0)} \left(1 - \overline{C}(0)\right) + \overline{c} - s(0) \]
Rearranging the terms,

\[
\overline{C}(0) + A(0)s^A(0) = [1 - A(0)s(0)] + A(0)c = C(0),
\]

where the right hand side gives the value of a default free bond with coupon \( \overline{c} \). Note that \([1 - A(0)s(0)]\) is the present value of receiving 1 unit at maturity \( t_N \). We therefore obtain:

**Pricing formula:**

\[
s^A(0) = \frac{1}{A(0)}[C(0) - \overline{C}(0)]
\]

\[
= \frac{C(0) - \overline{C}(0)}{\sum_{n=1}^{N} \delta_{n} B(0, T_n)}
\]
Chapter 8

Conclusion

The evolution of better models for credit risk measurement and better tools for credit risk management are mutually reinforcing: traditionally, without the tools to transfer credit risk, it was not possible to properly respond to the recommendations of a portfolio model. Conversely, without a portfolio model, the contribution of credit derivatives to portfolio risk-return performance has been difficult to evaluate. However, as such technology becomes more widespread, as the necessary data becomes more accessible and as credit derivative liquidity improves, the combined
effect on the way in which banks and others evaluate and manage credit risks will be profound. Banks have already adopted a more proactive approach to trading and managing credit exposures, with a corresponding decline in the typical holding period for loans. It is becoming increasingly common to observe banks taking exposure to borrowers with whom they have no meaningful relationships and shedding exposure to customers with whom they do have relationships to facilitate further business.

While it is true that banks have been the foremost users of credit derivatives to date, it would be wrong to suggest that banks will be the only institutions to benefit from them. Credit derivatives are bringing about greater efficiency of pricing and greater liquidity of all credit risks. This will benefit a broad range of financial institutions, institutional investors and also corporates in their capacity both as borrowers and as takers of trade credit and receivables exposures.

Given the growth potential of credit derivatives, this will initiate the development of a sounder regulatory framework for these instruments. No doubt, the quantitative technology used to price these instruments is an evolving process as the credit derivatives market becomes more complex and sophisticated.
Appendix

A pricing example of CDS’s: Market Valuation Approach

The following is a pricing example of a CDS using the methodology in section 7.4.

Let’s see how we can value a hypothetical CDS trade. Consider a 2-year CDS with quarterly premium payments. Assume a spread of 200 basis points per annum, and the discount factors and the survival probability for each payment date are as shown below:

</table>
**Fixed Leg: Fixed, periodic payments**

The present value of all expected fixed payments is found by multiplying each period’s fixed payment by the respective survival probability, discounted at the risk-free rate and summed over the term of the CDS. The PV in the table of R 37,268, is the present value of the fixed leg for a notional of 1 million rands.

**Fixed Leg: Accrual payments**

Assuming that default occurs, if any, at the middle of the time interval between two payment dates, the value of the accrued premium payment if a default occurs is a half of 50 basis points, or 25 basis points. Then, the expected value of the accrued payment for each period is 25 basis points multiplied by the probability of default for that period, as in column [7] in the table above. Discount these values for all periods and summing them over the term of the CDS, we get a value of R 141.48 (sum of column 8), which is the present value of expected accrued fixed payments.

From above, we can see that the present value of the fixed leg over the 2 year term is (R 37,268 + R 141.48) = R 37,409.33.

**Floating leg:**

The expected value of the floating payment if a default occurs during each period is $1 - \pi$ multiplied by the probability of default for that period (column [9]). Assuming a recovery rate of 30%, the expected contingent payment is multiplied by each period’s default probability. Discount this for each period and summing over the term of the
CDS, we get a value of R 39,613 as in column [10], which is the present value of the expected contingent payments.

Hence, we can find the value of this CDS to the protection buyer when the spread is 200 basis points per annum as:

R 39,613 – R 37,409.33 = R 2,203.68
